Abstract

Surface modification of cellulose nanocrystals (CNC) by organocatalysed grafting through ring-opening polymerization (ROP) of trimethylene carbonate was investigated. Organocatalysts including an amidine (DBU), a guanidine (TBD), an amino-pyridine (DMAP) and a phosphazene (BEMP) were successfully assessed for this purpose, with performances in the order TBD > BEMP > DMAP, DBU. The grafting ratio can be tuned by varying the experimental parameters, with the highest grafting of 74% by weight obtained in smooth conditions, *i.e* at room temperature in tetrahydrofuran with a low amount of catalyst. This value is much higher than that of typical ring opening polymerizations of cyclic esters initiated from the surface of cellulose nanoparticles. Additionally, DSC analysis of the modified material revealed the presence of a glass transition temperature, indicative of a sufficient graft length to display polymeric behaviour. This is, to our knowledge, the first example of cellulose nanocrystals grafted with polycarbonate arms.

Keywords:

1. Introduction:

Polysaccharides, and in particular cellulose, have experienced a rejuvenation of interest in recent years after being slowly replaced by petroleum alternatives during the 20th century in many applications. With the increasing concern over sustainability of many aspects of chemistry and materials science, the surge of interest in these materials is unsurprising as they constitute the bigger fraction of biomass (Habibi, Lucia, & Rojas, 2010). Cellulose nanoparticles in particular have received a lot of attention due to native cellulose availability and their interesting properties such as a high aspect ratio, high young modulus, and low density (Dufresne, 2013). Both cellulose nanofibrils (CNF) and cellulose nanocrystals (CNC) have been widely studied as fillers for composite materials since the work of Favier *et al.* in 1995 who reported on the first

composites reinforced with cellulose nanocrystals. Incorporation of nanocellulose into a polymer matrix has since been studied extensively and has the potential, especially when combined with biodegradable polymers, to produce strong yet fully biodegradable materials. To this end, carbonates are of particular interest, as aliphatic polycarbonates are highly valuable polymers with a very large scope of applications, most notably in textiles, biomedical applications, microelectronics, and packaging (Yu, 2021). As an additional benefit to being biodegradable (Artham & Doble, 2008), aliphatic polycarbonates have also been obtained from renewable sources making them valuable as a potential alternative to petroleum-based polymers (Helou *et al.*, 2010). To produce high performance composite materials, using nanocellulose directly as an additive to polymers has proven to give less than ideal results due to the highly hydrophilic nature of cellulose and its tendency to aggregate. These issues typically lead to a lower than expected mechanical strength and ductility as these are highly dependent on the dispersion of the reinforcing fibre in the polymer matrix and on the strength of the interface (Habibi, 2014).

To find solutions, a large amount of work has been carried out on the surface modification of cellulose nanocrystals, typically using the hydroxyl groups (Eyley & Thielemans, 2014) *via* acetylation (Xu, Wu. Z., Wu. Q., Kuang, 2020), carbamation (Girouard *et al.*, 2016), esterification (Trinh & Mekonnen, 2018), etherification (Sahlin *et al.*, 2018), silanization (Anžlovar, Krajnc, & Žagar, 2020), amidation (Lasseuguette, 2008), and polymer grafting by different methods. While "grafting to" polymerization, *i.e* the process of grafting a pre-synthesized polymer chain to the surface of cellulose can be successful (Azzam *et al.*, 2016), the "grafting from" method is usually the preferred pathway to cellulose modification with polymers as it is better controlled and avoids problems such as steric hindrance (Wohlhauser *et al.*, 2018). The "grafting from" approach has been used to couple many types of polymers on cellulose such as *e.g* polylactones (Habibi *et al.*, 2008; Labet & Thielemans, 2012) and polylactide (Lalanne-Tisné, Mees, Eyley, Zinck, & Thielemans, 2020). In the case of polymer grafting, the main goal is usually to increase the compatibility between the cellulose fibres and a polymer matrix (Thielemans, Belgacem, & Dufresne 2006). Lactones and lactides have received a lot of attention due to their potential in biomedical application (Albertsson & Varma, 2003) as they can undergo hydrolysis *in vivo*. However, polyester hydrolysis generates carboxylic acids, which can be a significant drawback (Lendlein & Langer 2002). Polycarbonates demonstrate much of the same advantages as polyesters when it comes to their degradation *in vivo* (Engler *et al.*, 2013) but they do not generate acidic products during hydrolysis (Kluin *et al.*, 2009). Despite their potential use, however, polycarbonate grafting has not seen much attention, with only some work on grafting on cellulose filter paper (Pendergraph, Klein, Johansson, & Carlmark 2014), synthesis of isosorbide-based polycarbonates (PC) in the presence of cellulose nanocrystals (Park *et al.*, 2019), and grafting of poly(trimethylene carbonate) from starch (Samuel *et al.*, 2014). To our knowledge, the grafting of aliphatic polycarbonates from the surface of cellulose nanocrystals has never been reported before.

89　To exert control over final properties, it is important to have a well-controlled polymerization reaction.

90　Therefore, the choice of a catalytic system with a high activity and a high level of control is a primary

91　concern. In the case of aliphatic polycarbonates, ring-opening polymerization (ROP) is currently the leading

92　approach as it leads to a living polymerization, therefore satisfying the criteria listed before, *i.e* high activity

93　and high level of control (Jerome & Lecomte, 2008; Penczek, Cypryk, Duda, Kubisa, & Slomkowski, 2007).

94　State of the art ROP allows for the use of many catalysts, including non-toxic metal centres like zinc.

95　However the presence of catalyst traces in the material produced is unwanted for many applications, and

96　metal catalysts are known for being hard to remove completely from polymeric materials (Hafrén &

97　Córdova, 2005). "Immortal" ring-opening polymerization is an approach that has been used for carbonate

98　polymerization and which allows for the use of a small amount of catalyst along with a co-initiator in the

99　form of a protic source. This co-initiator determines the number of chains growing, which gives control over

100　the chain length no matter the quantity of catalyst used while keeping a high catalytic activity (Helou,

101　Miserque, Brusson, Carpentier, & Guillaume, 2008). This approach can also be carried out metal free, as

102　many advances in organocatalysis have led to the emergence of a wide variety of ROP catalysts (Ottou,

103　Sardon, Mecerreyes, Vignolle, & Taton, 2016). While not all these systems are as efficient as metallic

104　catalysts, some are very promising and have shown a high degree of control. In the case of aliphatic

105　carbonates, and in particular trimethylene carbonate (TMC, see Figure 1), base catalysts have been reported

106　to produce polycarbonates with low dispersity (Kamber *et al.*, 2007). Catalysts of interest include amines

107　(dimethylethanolamine, 4-dimethylaminopyridine-DMAP), guanidines (1,5,7-triazabicyclo[4.4.0]dec-5-

108　ene-TBD), amidines (1,8-diazabicyclo[5.4.0]undec-7-ene-DBU), and phosphazenes (2-*tert*-butylimino-2-

109　diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine-BEMP) among others (Helou *et al.*, 2010;

110　Lohmeijer *et al.*, 2006). While ring-opening polymerization of trimethylene carbonate with organic catalysts

111　has been studied extensively in the last decade, small protic molecules such as benzyl alcohol were mostly

112　used as the co-initiator (Helou *et al.*, 2010). Therefore, using cellulose nanocrystals as the protic source to

113　obtain a brush copolymer with polycarbonate is an interesting perspective. Understanding of the reaction

114　and the influence of different parameters would be valuable to increase the general efficiency of polymer

115　grating on cellulose, a process with a generally low yield (Lalanne-Tisné *et al.*, 2020). In particular, to our

116　knowledge, trimethylene carbonate has never been grafted on the surface of cellulose nanocrystals before.

117　Hence, we report the first synthesis of poly(trimethylene carbonate) grafted cellulose nanocrystals *via* ring

118　opening polymerization and investigate the influence of experimental parameters in an effort to increase the

119　grafting efficiency.

2. Materials and Methods

2.1. Materials

Sulfuric acid (97%) was obtained from VWR and calcium hydride was purchased from Acros Organics. Dichloromethane and ethanol (analytical reagent grade) were obtained from Carlo Erba and cotton wool was obtained from Fischer Scientific. Benzoic acid (99%) and tetrahydrofuran were obtained from Sigma Aldrich and purified through alumina column (Mbraun SPS). 2-*tert*-Butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine (BEMP, 98%) was also obtained from Acros Organics. 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU, 99%) was bought from Alpha Aesar and 1,5,7-Triazabicyclo[4.4.0]dec-5-ene (TBD, >98%) from TCI. BEMP, DBU and TBD were introduced, opened and stored in a glovebox and used as received.

Trimethylene carbonate (TMC, 99.5%) was purchased from Actuall Chemicals and purified by drying over calcium hydride, filtered under inert atmosphere and then recrystallised. The purified monomer was subsequently stored in a glovebox. 4-Dimethylaminopyridine (DMAP, 99%) was purchased from Aldrich and co-evaporated three times with toluene followed by sublimation under vacuum at 85°C and stored in a glovebox before use.

All chemicals were used as received unless stated otherwise.

Preparation of CNCs

Cotton nanocrystals were prepared by acid hydrolysis of cotton wool for 35 min at 45°C in a 64 wt% aqueous H_2SO_4 solution while stirring constantly (Revol *et al.*, 1992). Deionised water was used to wash the resulting suspension by three successive centrifugations at 10 000 rpm and 10°C for 40 min, replacing the supernatant with deionised water each time. Dialysis under continuous tap water flow was then used to remove residual free acids. After 48 h, the pH of the eluent was checked to be neutral and a homogeneous dispersion of cotton nanocrystals in water was obtained using a Branson sonicator at 10% amplitude for 2 min. The dispersion was subsequently filtered over a fritted glass filter no. 2, and stirred overnight with Amberlite MB-6113 resin to remove non-H_3O^+ cations. The dispersion was sonicated one last time, frozen in liquid nitrogen, and freeze-dried using a Heto PowerDry PL6000 apparatus from Thermo Scientific under a vacuum of 2 bars. In addition to this procedure commonly followed in the literature to prepare cellulose nanocrystals, a further purification was performed to remove surface adsorbed impurities that adsorb onto the nanocrystal surface (Labet & Thielemans, 2011). After freeze-drying, the cotton nanocrystals were Soxhlet extracted for 24h using ethanol as a solvent. The nanocrystals were subsequently dried in a vacuum oven (0.5 bar) at 50°C and then dried further under ultra-high vacuum (Pfeiffer DCU 100) at 10^{-6} bars for 4

153 days. The container used for the drying process was then tightly closed, filled with argon, and placed in a
154 glovebox.

2.2. Ring-opening polymerization of TMC on CNC surface

156 All experiments were carried out under inert atmosphere in a glovebox unless stated otherwise.
157

158 *Figure 1:General reaction scheme of the ring-opening polymerization of trimethylene carbonate co-initiated by hydroxyls present*
159 *on the surface of cellulose nanocrystals*

160 In a typical reaction, a stir bar was placed in a small reactor, along with a specified amount of CNCs. The
161 molar ratio used are specified in Table 1 and Table 2 and based of the molecular weight of one glucose ring
162 bearing one primary OH. THF was added and the mixture was stirred for 30 minutes to disperse the CNCs.
163 Trimethylene carbonate was then added and left to stir until complete dissolution. Subsequently, the catalyst
164 was added while stirring and the reactor was placed in an oil bath set at a given temperature. After the
165 desired duration, the reaction was quenched using benzoic acid and dichloromethane addition, and the
166 mixture was filtered through a Soxhlet extraction thimble. A sample of the crude mixture was taken for
167 NMR analysis, and the modified CNCs were purified by Soxhlet extraction twice, first with
168 dichloromethane (24 hours), and then with ethanol (24 hours).

169 The modified nanocrystals were then dried under vacuum on a Schlenk line (< 1 mbar) for 24 hours.

170 The homopolymer produced as a side reaction was recovered from the first Soxhlet extraction mixture after
171 evaporation of the dichloromethane.

172 Characterization methods, apparatus, calculation method to determine grafting, conversion and yield, and
173 additional information about experimental procedures are all available in Supporting Information Appendix
174 A.

3. Results and discussion

3.1. Catalyst screening

[f] Molar mass distribution calculated from SEC of homopolymer.

The performances of the different organic catalysts, namely TBD, BEMP, DMAP and DBU (shown in Figure 2) to polymerize TMC from the surface of cellulose nanocrystals were evaluated in THF at room temperature. The different catalysts were selected from their ability to catalyse ROP of TMC in the presence of an alcohol (Helou et al., 2010). The TMC/catalyst/OH ratio was mostly kept at 500/1/50. Table 1 displays the most significant results.

In the absence of catalyst, significant conversion of the monomer into either grafts or homopolymer was not achieved (Table 1, entry 1), showing the clear need to use a catalyst.

BEMP pKaH$^+$: 27.5

TBD pKaH$^+$: 26.2
DBU pKaH$^+$: 24.3

DMAP pKaH$^+$: 17.95

Figure 2: Structure of the organocatalysts used in this study. pKa values in acetonitrile (Ishikawa, 2009; Kaljurand et al., 2005)

184   At a typical ratio of 500/1/50 (TMC/catalyst/OH), TBD was shown to reach full conversion of the monomer

185   within 5 hours, and resulted in modified CNCs containing of 51% grafted polymer (Table 1, entry 2), a

186   fairly high value for typical "grafting from" of polymer through ring opening polymerization from the

187   surface of nanocellulose. Similarly, a significant amount of monomer was converted to homopolymer (yield

188   of 16% for grafting), which shows an important competition between grafting of the monomer and

189   homopolymerization. However, it is common for grafting on cellulose to use a large excess of monomer to

190   increase the amount of grafting at the cost of efficiency (Lalanne-Tisné, *et al.*, 2020; Miao & Hamad, 2016).

191   Molar mass dispersity of the homopolymer was found at an acceptable value of 1.8 that is significantly

192   higher than usual values obtained for typical homopolymerizations (Nederberg *et al.*, 2007). The broader

193   distribution can be explained because it is a side reaction involving water and ethanol as co-initiatiors that

194   are still entrapped in the CNCs after purification. In addition, water and ethanol can also be involved in

195   hydrolysis and transcarbonatation reactions respectively. This can be seen from the MALDI ToF mass

196   spectra of the precipitated polymer showing the corresponding chain ends (details in Supporting Information

197   Appendix A).

198   Using similar reaction conditions for BEMP (entries 3-5), a phosphazene catalyst, showed quite different

199   results. Full conversion was not reached, and after increasing the reaction time from 3 to 5 hours, BEMP

200   conversion only reached 52%. Further increasing the reaction time to 16 hours did not increase monomer

201   conversion. Despite the lower conversion values, grafting on cellulose was achieved with this catalyst, and

202   up to 37% grafts were achieved in the modified CNCs, showing that this catalyst, while less efficient than

203   TBD using similar parameters, leads to substantial grafting.

204   The reactions conducted with DMAP (entries 6-8) and DBU (entries 9-10) did not perform as well as the

205   others under the same reaction conditions (room temperature, 5h), with NMR analysis showing very low

206   conversion. The resulting grafting was rather low for both catalyst (18% maximum) under these conditions,

207   and no oligomers could be recovered by precipitation to allow for SEC analysis. This is believed to be due

208   to their likely low average molecular weight.

209   We can try to explain the superior performance of TBD. TBD, unlike the other catalysts tested, possesses a

210   secondary amine group, giving it great potential for catalysis *via* hydrogen bonding. It is also interesting to

211   note that unlike DBU, which can operate by a basic and a nucleophilic mechanism, TBD can catalyse

212   transesterification reactions by dual activation *via* H-bonding (Simón & Goodman, 2007; Stanley et *al.*,

213   2019). Having a catalyst that can use both mechanisms may result in a better reaction due to the ability of

214   the catalyst to go in between intermolecular bonding (similarly to how a protic solvent gives a better

215   dispersion of CNCs). In addition, DBU and DMAP may favour homopolymerization due to their ability to

216   perform a nucleophilic attack on the monomer, which is not the case for the BEMP phosphazene, that leads

217   to an intermediary grafting ratio.

218   When looking at results for homopolymerization of trimethylene carbonate (Helou et *al.* 2010), it is worth

219   noting that TBD is also the most active catalyst in bulk, and full conversion is achieved much faster at lower

220   temperatures when compared to DMAP and DBU. As the work presented here is carried out in solvent but

221   at room temperature, it is possible that the activity of some of the catalysts (except for TBD) is reduced as

222   the activation requires more energy. However, further testing at higher temperature with all the catalyst was

223   not explored as we observed browning of the CNC at temperatures as low as 40°C in the presence of THF

224   and TBD (see next section).

225   Comparing the pKa of all 4 bases, TBD in acetonitrile does not come up as the strongest base (25.96), with

226   BEMP having a higher pKa (27.5), despite its superiority when it comes to grafting TMC on cellulose. TBD

227   is however a stronger base than DMAP and DBU, which could explain partially the better results obtained

228   when comparing these 3 bases. As for BEMP, it is a much bulkier catalyst, therefore steric hindrance may

229   be the cause for the lower activity when compared to TMC, in particular for the grafting onto CNC. This

230   can be exemplified as despite the subpar grafting efficiency on CNCs with BEMP, the extracted

231   homopolymer showed a higher M_n that the homopolymer recovered after full conversion with TBD.

232   As the screening of catalysts showed a more efficient grafting with TBD, this reaction was studied further,

233   in order to assess the influence of the reaction conditions.

234   **3.2. Influence of experimental parameters for the TBD catalysed grafting**

235   As the polymerization of TMC has also been performed in bulk (Helou et *al.*, 2010), the grafting reaction

236   on the surface on CNCs was also carried in bulk as comparison (entry 11, Table 2). Despite

237   homopolymerization of TMC being very quick under bulk conditions, the reaction with cellulose did not go

238   to full conversion within an hour. However, the polycarbonate content of modified CNCs did reach 47%, a

239   value comparable to the content obtained by grafting in THF. The viscosity is a major issue in bulk reactions

240   as the melted monomer is not a good medium to disperse CNCs, resulting in poor homogeneity of the final

241   material and a greater difficulty to redisperse the modified cellulose in solvent, rendering its use more

242   complicated. The high viscosity is also likely a cause for the lower conversion, as the reaction slows down

243   considerably with homopolymer production. Lastly, the bulk reaction, as expected, shows a much higher

244   dispersity for the synthesized homopolymer, indicating some loss of control over the polymerization

245   reaction.

246 THF was used as the main solvent as it had shown to dissolve well TBD, TMC, poly(trimethylene

247 carbonate), and to be a good solvent for CNC dispersion. Some other common solvents were assessed, but

248 worse results were obtained (additional information in SI).

[e] Determined by SEC of homopolymer *vs*. polystyrene standards and corrected with a correction factor of 0.57, 0.73, or 0.88 based on size measured (Palard et *al.* 2007). [f] Molar mass distribution calculated from SEC of homopolymer. [g] Bulk reaction. [h] Reaction done over 24 hours instead of 5. [i] Reaction performed outside the glovebox. [j] Stirred for 24h and sonicated prior to reaction to maximize dispersion of CNC. NA: not available as oligomers, i.e too short to precipitate in cold methanol

250 As shown previously (entry 11), the polymerization of TMC was total after 5 hours, however a reaction in

251 similar conditions was also performed over 24 hours (entry 12) to evaluate the activity of TBD over longer

252 period of time, as it has been reported to be capable of depolymerization (Meimoun et *al.*, 2020). In the case

253 of poly(trimethylene carbonate) grafted CNCs, a small increase in grafting content can be measured after

254 24 hours of reaction, however the average molecular weight of the produced homopolymer started

255 decreasing, showing potential signs of depolymerization or transcarbonation reactions. Therefore 5 hours

256 was the favoured reaction time for most reaction, as it allowed for a good control over grafting while having

257 good conversion, and a very good reproducibility (repeated reactions available in SI).

258   At the typical ratio of TMC/Cat/OH of 500/1/50, variation in temperature was tested to determine its

259   influence on the grafting reaction. At first glance, the temperature did not appear to change the mount of

260   grafting by a significant amount, as increasing the temperature to 40°C (entry 14) or 60°C (entry 15) yielded

261   CNCs with 51% and 52% grafts respectively (compared to entry 2). However, at temperatures as low as

262   40°C, browning of the CNCs was observed and became more pronounced at higher temperature, indicating

263   a potential degradation of the material. A shortening of the homopolymer chains is further observed as the

264   reaction temperature increases, indicating of possible depolymerization / chain scission reactions in the

265   presence of TBD, which has been reported for both polycarbonates (Li, Sablong, van Benthem, & Koning,

266   2017) and polylactides (Meimoun et *al.*, 2020). A reaction at 0°C was also performed using an ice bath to

267   determine if a lower temperature could favour grafting over homopolymerization (entry 13), however the

268   results obtained for the grafting of CNC were in the same range (>50%) as the reaction performed at room

269   temperature (RT). The temperature used for the rest of the reaction was therefore set to RT (controlled by

270   an oil bath) to avoid any degradation of the material and to keep the reaction more energy efficient.

271   A reaction was then performed under inert atmosphere, but not under glovebox conditions, to evaluate how

272   sensitive the efficiency of the grafting was regarding the presence of water and other impurities (entry 16).

273   Prior to the reaction, CNCs and TMC were dried using a vacuum and an argon line rather than ultra-high

274   vacuum. THF was used after purification over alumina, similarly to experiments performed inside the

275   glovebox. Multiple argon/vacuum cycles were used to ensure inert atmosphere was achieved. Under these

276   conditions, a low amount of grafting (7 vs. 51% in entry 2) as well as the short chain length of the

277   homopolymer (impossible to precipitate in cold methanol) showed the prevalence of initiation by traces of

278   water and ethanol. Due to CNCs being hydrophilic, it is hard to remove significant traces of water from

279   them without extreme conditions (10^{-6} bar of vacuum), as well as ethanol from the purification steps of

280   preparing CNCs. This reaction shows that in order to maximize grafting efficiency purification of the

281   different chemicals a thorough drying of the cellulose is required, and working in a glovebox is useful.

282   In an attempt to increase grafting on cellulose, reactions were then performed with an increased ratio of

283   TMC/CNC by decreasing the quantity of cellulose used. Surprisingly, increasing the quantity of monomer

284   did not lead to a significant improvement in the grafting amount on cellulose (entries 17-18), which seems

285   to reach a maximum at around 50%, a result similar to other reactions (entry 2). This shows that simply

286   increasing the quantity of monomer used in the reaction is an ineffective way to increase the maximum

287   amount of grafting on the surface of CNC.

288   To determine if the availability of the hydroxyl groups on the surface of cellulose is an important factor, a

289   reaction was performed on a batch of CNC in THF with increased effort at individualization of CNCs. The

290   mixture of cellulose and solvent was prepared in the glovebox, then closed tightly and stirred over 24 hours

vs. 30 min previously used. A sonication bath was also used in burst of 5 minutes over the 24 hours. The results obtained (entry 19) when compared to a "typical" reaction showed that increased effort for maximum individualization of CNCs did not have a significant impact as the grafting obtained was also around the 50% mark.

The influence of catalyst loading was further assessed. Using a typical ratio TMC/TBD/OH of 500/1/50 showed good results and a grafting of around 50%. Increasing the catalyst ratio to 2 equivalents *vs.* OH (entry 20) however lowered the grafting % on CNCs by a significant amount, whereas the length of the homopolymer increased, indicating that increasing the TBD amount favours homopolymerization. Increasing the amount of catalyst further to 5 equivalents (entry 21) yielded a similar amount of grafting onto the CNCs than entry 20 (9%), but the average molecular weight of the isolated polymer was significantly smaller (< 3000 g.mol^{-1}). As mentioned previously, TBD is not only capable of polymerization, but also depolymerization under the right circumstances *via* a nucleophilic attack on the carbonyl moieties (Meimoun et *al*. 2020). In the case of polylactide, the use of 5 equivalents of TBD decreased the average molecular of the resulting polymer more than tenfold, a result very similar to what is observed in this work for the polycarbonate.

As opposed to increasing the catalyst quantity, lowering the amount of TBD used for the reaction to 0.5 equivalents showed an improvement in the grafting on CNCs with a material composed of up to 74% polycarbonate grafts by weight and a grafting yield of 46% (entry 22). M_n of the homopolymer obtained was lower, which can simply be explained by the increased quantity of monomer turned into grafts rather than homopolymer.

Decreasing the quantity of catalyst further resulted in a decrease in the amount of grafting to 64% (entry 23), which is an improvement over the result obtained with 1 equivalent (entry 2) but a setback compared to reactions performed with 0.5 equivalent (entry 22). Moreover, the low concentration of TBD led to a slower reaction, and obtaining full conversion became more difficult.

To improve the grafting efficiency with respect to the total amount of monomer used, reactions with 0.5 equivalent of TBD (shown to have the best results) and successively lower amounts of monomer were carried out.

The grafting % decreased from 74% to 57% (entry 22 *vs.* 24) when the monomer concentration was halved, but the grafting yield stayed within the same range at 42%. While this is not an improvement, it however, allows one to obtain CNCs with around 50% grafts with significantly less monomer loss than some previous experiments (*e.g* entry 2). Lowering the amount of monomer further continued to reduce the % grafting

322   (47%) but led to an increased yield of 56% which is a good value for grafting of a polymer on cellulose, as

323   this parameter is usually overlooked in favour of trying to reach a maximum amount of grafting.

324   A similar reaction was also performed with a typical 1 equivalent TBD to compare to the grafting yield

325   obtained with 0.5 equivalents. As previously shown, the grafting % obtained is superior using a lower

326   quantity of catalyst, leading to a higher grafting yield.

327   Overall, this shows that a wide range of grafting % is possible, and specific values can be targeted using the

328   right amount of catalyst (typically 0.5 eq) without having to use a large excess of monomer, while keeping

329   the grafting yield as high as possible.

330   **3.3. Characterization of the poly(trimethylene carbonate)-grafted CNC as a function of**

331   **the grafting ratio**
Figure 3: FT-IR spectra of unmodified cellulose nanocrystals (CNC) and grafted one with different graft content after purification by Soxhlet extraction.PTMC of 154000 g/mol extracted from soxhlet and purified by precipitation. Grafted CNCs corresponding to refe

332

333   In addition to elemental analysis, FT-IR was used to determine the success of the grafting reaction (Figure

334   3). As expected, both modified and unmodified cellulose spectra resemble each other. However, 2 bands

335   characteristic to our grafts are visible for modified cellulose. First, the band at 1754 cm^{-1} can be identified

336   as a carbonyl stretch ν(C=O), thus confirming the successful incorporation of the carbonate moieties onto

337   CNCs. A second characteristic band is observed at 1229 cm^{-1} corresponding to ν(C-O) stretching (Nyquist

338   & Potts, 1961). As shown in Figure 3, the relative intensity of both bands increased with the grafting content,

339   thus confirming the results determined by elemental analysis and TGA. Lastly, the ratio of absorption band

340   at 1059 cm^{-1} corresponding to ν(C3-OH) to C-O-C stretching at 1160 cm^{-1} (Marechal & Chanzy, 2000),

341   decreases with increasing grafting ratio which shows the successful esterification of the secondary alcohol

342   in the C3 position. The band at 1032 cm^{-1} corresponding to ν(C6-OH) increases with increasing grafting

343   ratio, as terminal OH of the polycarbonate chains appear in this region as well. As a consequence, grafting

344   on the C6 position is not "visible" by FTIR, as both primary and secondary C-OH of cellulose are replaced

345   by the primary terminal C-OH of the polymer at 1032 cm^{-1}. Note that ν(C2-OH) cannot be discussed here

346   as the polymer has a band in the area.

347   X-ray photoelectron spectroscopy can give additional insight into the composition of the modified CNCs at

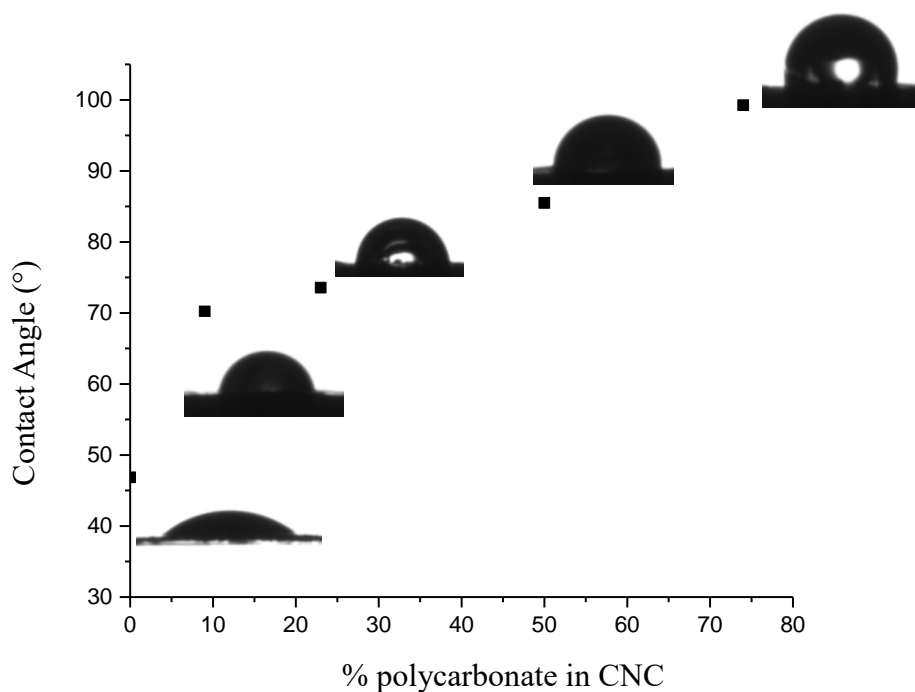

Figure 4: Carbon 1s X-ray photoelectron spectroscopy (XPS) scan of
cellulose nanocrystals grafted with different poly(trimethylene carbonate
content). Grafted CNCs corresponding to reference in Table 2: entry 26
(23%) entry 28 (41%), entry 23 (64%), entry 22 (74%

348   a surface level. In the C1s high resolution scan (Figure 4), the aliphatic C-C carbon contribution (C1) at 285

349   eV is shown to increase rapidly with grafting, as cellulose units do not contain aliphatic carbons, unlike

350   trimethylene carbonate. With an increasing amount of graft content, the relative intensity of the C1

351 contribution increases and then appears to reach a maximum, at the contribution amount expected for pure

352 poly(trimethylene carbonate) chains indicating that no cellulose contribution is visible anymore. As opposed

353 to C1, the C2 and C3 contributions to the C1s signal, corresponding to C-O and O-C-O environments

354 respectively, both decreased with an increasing amount of grafts, as poly(trimethylene carbonate)

355 contributes less to the C-O signal than cellulose, and does not contribute to the O-C-O signal. Finally, the

356 O-C=O contribution (C4) increased with grafting content, similarly to C1 as the carbonate function is the

357 only contribution to this peak. The results obtained from elemental analysis, along with form of

358 characterization are therefore confirmed with the XPS data.

359 With poly(trimethylene carbonate) being a highly hydrophobic material, grafting CNCs with it will change

360 its interaction with water significantly. To quantify this, grafted CNCs were used in contact angle

Figure 5: Contact angle of a water droplet on the surface of CNC modified with different polycarbonate content. Grafted CNCs corresponding to reference in Table 2: entry 9 (9%) entry 26 (23%), entry 2 (51%), and entry 22 (74%)

361 measurements with water. The water contact angle increased rapidly with the poly(trimethylene carbonate)

362 content of the cellulose sample (Figure 5), in line with the length of the graft in the brush copolymer

363 structure. For a poly(trimethylene carbonate) content as low as 9%, the increase in hydrophobicity is

364 significant, which then increases more slowly as the carbonate content increased, up to a value close to that

365 of pure PTMC reported in the range 90-110°C (Brossier et al., 2021; Yao et al., 2017). This might be related

366 to an increasing coverage of the CNC by PTMC, ranging from partial to almost full. It is noteworthy that

367 the contact angle and thus the wettability can be controlled by targeting the proper polycarbonate grafting

368 ratio. As a result, we believe that this increase in hydrophobicity shows good signs for the potential

369 incorporation of these nanoparticles in a polymer matrix for composite applications.

Figure 6: Differential Scanning Calorimetry graphs of CNC, poly(trimethylene carbonate) (PTMC) and modified CNC during the second heating at 10°C/min. . Grafted CNCs corresponding to reference in Table 2: entry 26 (23%), entry 2 (51%), and entry 22 (74%)

370 DSC analyses were conducted to obtain more information on the thermal behaviour of the grafts. The

371 samples were heated from -80 to 190°C, as the glass transition temperature (T_g) of poly(trimethylene

372 carbonate) is below 0 °C. For unmodified CNCs, no T_g or melting point were observed, as expected (Figure

373 6Figure 6). For grafted CNCs, a glass transition was observed for all samples in the same range as the T_g of

374 pure poly(trimethylene carbonate), but with slightly higher values. With a graft content as low as 23%, a T_g

375 at -9°C can be recorded, indicative of the presence of poly(trimethylene carbonate) grafts. As the carbonate

376 content increased, the T_g decreased and progressively moved towards the value for poly(trimethylene

377 carbonate) homopolymer (11700 g.mol^{-1}) at -17°C, without ever reaching it. This phenomenon could be

378 attributed to a lower mobility of the chain closer to the CNC backbone, their relative amount decreasing

379 with higher grafting values. Overall, this shows that polymer grafts on cellulose nanocrystals are of

380 sufficient length to showcase polymeric behaviour. In addition, we also measured the T_g of non-grafted

381 homopolymers of similar molecular weight and compared it with that of the grafted polymer (see SI section

382   S12). The 3 homopolymers of *ca.* 20 000 g/mol show a T_g of *ca.* -16/-17 °C, whereas the T_g of the grafted

383   CNC are in the range -10 to -13°C, which tend to confirm the occurrence of a true grafting.

384   In order to know whether the cellulose nanocrystals retain their structure following grafting, wide-angle X-

385   ray scattering was used to determine the crystallinity of the pristine and PTMC grafted CNC samples. The

386   X-ray scattering data was fitted with the crystal structure of cellulose Iβ, and the amorphous contribution to

387   the scattering determined. As no melting peak was seen in the DSC data, we know that the PTMC will be

388   included in the amorphous contribution to the scattering data. Therefore, considering the amount of PTMC

389   in the sample, changes in crystallinity of the cellulose ($\Delta\chi_{c,\,cellulose}$) can be determined as the difference in

390   crystallinity between the starting material and the product ($\Delta\chi_{c,\,sample}$), minus the expected contribution from

391   PTMC (φ_{PTMC} – the volume fraction of PTMC) as shown in Table 3.

392   *Table 3: The calculated sample crystallinity based on WAXS measurements for all samples*

Sample	$\chi_{c,\,sample}$	$\Delta\chi_{c,\,sample}$	φ_{PTMC}	$\Delta\chi_{c,\,cellulose}$
Unmodified CNC	0.99	-	0	0
23% PTMC-g-CNC	0.68	-0.31	0.27	-0.04
41% PTMC-g-CNC	0.56	-0.43	0.46	0.03
51% PTMC-g-CNC	0.37	-0.62	0.56	-0.06
64% PTMC-g-CNC	0.26	-0.73	0.69	-0.04
74% PTMC-g-CNC	0.14	-0.85	0.78	-0.07

393   The data on the grafted samples shows only around 5% change in cellulose crystallinity when the

394   contribution from amorphous PTMC is removed. This change could be due to peeling of the surface chains

395   of the CNC during grafting, however, given the lack of trend in $\Delta\chi_{c,\,cellulose}$, and the wide standard deviation

396   in the values, it is possible that this reflects the error in the calculation of the sample crystallinity by this

397   methodology.

398

399   **Conclusion**

400   Ring-opening polymerization (ROP) of trimethylene carbonate was performed using cellulose nanocrystals

401   as a co-initiator in the presence of 4 organocatalysts, *i.e* DMAP, DBU, TBD and BEMP). The overall

402   performances considering conversion, grafting ratio and yield are TBD > BEMP > DBU, DMAP. After

403   optimization, a grafting ratio as high as 74% could be reached using TBD, corresponding to a material

404   composed by weight of almost ¾ polycarbonate grafts. The reaction was performed at room temperature

405   with a low concentration of the catalyst, 0.5% vs. TMC and 500 equiv. TMC per glucose unit. This led to a

material with T_g and contact angle close to that of poly(trimethylene carbonate). The use of a single step reaction, under mild conditions while keeping grafting yield high is of great interest to produce CNC with a controlled amount of grafts. Furthermore, we were able to show some of the most influential parameters with respect to grafting content, providing some insight on the chemistry behind cellulose modification. The contact angle can be tuned from *ca.* 50 to 100° by adjusting the grafting ratio. Lastly, DSC results revealed the polymeric behaviour of the grafts, confirming the successful grafting of polycarbonate chains of sufficient length to have high potential as reinforcement fillers in composite materials. To our knowledge, this is the first reported chemical modification of cellulose nanocrystals with trimethylene carbonate, and the first example of a ROP-based grafting from process attaching polycarbonate chains onto CNCs.
